Abstract: Apart from protection from very high altitude or influence of increased gravitational accelerations protective suits sometimes are used for another applications like supporting kinesitherapy. Because of some safety considerations connected with possible cardiovascular system overload and dangerous blood pressure increase we tested if these concerns are valid. Main aim of presented research performed with participation of healthy volunteers was to confirm that use of High Altitude Protection (HAP) suit is safe in terms of increased cardiovascular.

Keywords: altitude protection suit, kinesitherapy, cardiovascular load, therapy safety
INTRODUCTION

High altitude protection suits (HAP suits), sometimes called also pressure suits, are devices designed and normally used for protection of aircrew in case of emergencies connected with exposition for very low atmospheric pressure (e.g. lost of cabin pressure at high altitude). The need for mechanical compression on the wearer body arises from two reasons. First, at the altitudes above around 10,000 m (33,000 ft) breathing even 100% oxygen under atmospheric pressure at such altitude does not meet human organism needs and oxygen must be administered under pressure greater than surrounding atmospheric pressure. Such condition, called positive pressure breathing (PPB), can lead to lung and thorax distension or even risk of lung tissue rupture hence there is need for external compression on the chest to balance intrapulmonary pressure. Secondly, at even higher altitudes – around 18-19000m (60-62000ft) there is a risk of boiling of exposed body liquids. Pressure at such altitudes is low enough (around 47mmHg) to allow water boiling in temperature of human body. For protection of life at such altitudes both positive pressure breathing and external pressure on the body is critically required.

Apart from being a safety device, high altitude protection suits sometimes are used in another applications like increasing blood pressure in vertical position in person after lengthy microgravity exposure or in kinesitherapy as a supporting devices for persons with antigravitational muscles deficits [4]. Additional advantage of using body compression techniques is concurrent both muscular and proprioceptive stimulation ongoing during therapeutic session [7]. Overall view of suit is present on fig. 1, it’s principle of operation is shown on fig. 2.

Major safety concern in normobaric and non-emergency conditions is increased blood pressure and breathing difficulties caused by high mechanical pressure on the wearers body.

Use of pneumatic assembles exerting the force on body in kinesitherapy is not frequent and the bibliography associated with this subject is scarce. Main system used in this application is Russian “Atlant” system [2]. We did not find any publications concerned on safety of their use, especially in terms of possible cardiovascular overload of patients involved. Some available data [1,6] suggest, that inflation below 70mmHg is completely safe in terms of significant blood pressure increase.

As a part of broader project in area of kinesitherapy we tried to investigate if wearing HAP suit inflated to pressures from range planned for future experiments is safe in terms of cardiovascular burden put on the participants organisms. Main aim of this paper is to assess performed research results in terms of safety to the suit wearer expressed with increase of HR and RR within safe limits.

MATERIAL AND METHODS

In presented work we used WUK-90 high altitude protection suit (Air-Pol, Legionowo, Poland). It is a capstan-type suit. In this system compression over the body is done through inflating rubber tubes which are increasing pressure on the body with non distending tapes sewn into suit fabric. In addition suit is equipped with abdominal bladder exerting pressure on lower abdomen and frontal pelvic region. Precise adjustment of suit is done with use of polypropylene laces. Closing of suit is done by means of metal zippers.

Therefore increasing of air pressure in capstan system and abdominal bladder is increasing mechanical force exerted by suit on the body of person wearing it.

Before experiments we obtained written approval from Military Institute of Aviation Medicine in Warsaw Ethics Committee in accordance with the Helsinki Declaration of 1975, as revised in 2000. Each participant signed informed consent...
In second stage results were confirmed with group of 17 healthy volunteers who performed one real kinesitherapy session with use of the HAP suit. Mean age of control group was 29,5 years of age (SD ± 4,69y; age span was from 23 to 41 y.o.). Eight females and nine males constituted our control group.

Each participant has systolic and diastolic blood pressure measured (with OMRON™ R7 blood pressure monitor), arterial blood saturation SpO2 (with finger pulse oximeter). Results were recorded and analyzed with paired t-tests. Measurements of blood pressure were taken 5 min before donning of HAP suit and after that RR and SpO2 measurements were taken in 3 minutes intervals. Each examination were 24 minutes long. Last measurements were taken 5 minutes after HAP removal.

RESULTS

As a starter we tried investigation with one volunteer using inflated WUK on the treadmill normally used for stress test cardiology. Physical load was in accordance with Bruce protocol [5]. Physical workload was increased in 3min intervals. Increase was both in terms of speed and angle of elevation. Stages of exercise test are presented on table (tab. 1) below:

Our subject has attained Stage 4 according to this protocol. Measurements of systolic and diastolic pressures are provided on graph (fig. 4) below:

Control group of 17 volunteer participants were tested in similar manner, but we broadened measured parameters with pulse oximetry. During 24
minutes of measurements period participants performed sets of physical exercises designated for patients (research) group. Results of control group parameters after exercises are presented below (fig. 5 & 6):

Results obtained indicate, that blood pressure changes (both diastolic an systolic) were on minuscule level (- well below 1%) (table 2), p=NS.

**DISCUSSION**

Main safety concern associated with use of compressing devices, especially if they cover chest region is increase of blood pressure resulting from addition of mechanical external pressure to the “normal”, heart generated blood pressure. In physiological condition blood pressure is regulated on correct level by reflex from carotid baroreceptors. Distending of carotid artery walls caused by increased blood pressure activates heart inhibition, mainly through vagal nerve. In opposite situation decreased blood pressure on carotid receptor is inhibiting parasympathic activation of vagal nerve thus increasing heart output. This is phenomenon thoroughly studied during head-foot directed acceleration exposures in flight or on the centrifuge.

Short Communication

This is quite powerful reflex, allowing human body to compensate lower body blood retention up to around four times Earth’s gravity. In experiments described in this paper we wanted to check if potential of this reflex going the opposite way i.e. decreasing heart’s output in conditions of increased pressure is enough to allow overall blood flow close to normal. Because of systemic nature of the reflex we have chosen wrist blood measurement instead of neck pressure measurements, which are more technically complicated and hardware involved is precluding free movements necessary to perform therapeutic exercises. From centrifuge experiments we know, that use of height compensated limb pressure measurement is sufficient to assess both heart and brain level blood pressure.

All performed measurements have confirmed that use of WUK-90 high altitude protections suit is safe in terms of cardiovascular system parameters in area of pressures used in experiments. We did not encountered any increase of blood pressure which may be considered as a harmful, for participants.
